In Brief

Shimojo et al. investigated mechanisms of protein secretion in central neurons. They identified SNAREs that drive the vesicular exocytosis of BDNF, a secreted factor involved in neural circuit development and plasticity. Loss of BDNF or SNAREs that promote BDNF release in callosal cortical neurons impairs the development of their axons.

Highlights

- BDNF is a secreted protein that regulates neuronal development and plasticity
- Vesicular exocytosis of BDNF is driven by SNAREs, Syb2, SNAP25, and SNAP47
- Unlike Syb2 and SNAP25, SNAP47 appears to be unnecessary for neurotransmission
- Loss of BDNF or SNAP47 in callosal neurons diminishes branching of their axons

SNAREs Controlling Vesicular Release of BDNF and Development of Callosal Axons

SUMMARY

At presynaptic active zones, exocytosis of neurotransmitter vesicles (SVs) is driven by SNARE complexes that recruit Syb2 and SNAP25. However, it remains unknown which SNAREs promote the secretion of neuronal proteins, including those essential for circuit development and experience-dependent plasticity. Here we demonstrate that Syb2 and SNAP25 mediate the vesicular release of BDNF in axons and dendrites of cortical neurons, suggesting these SNAREs act in multiple spatially segregated secretory pathways. Remarkably, axonal secretion of BDNF is also strongly regulated by SNAP47, which interacts with SNAP25 but appears to be dispensable for exocytosis of SVs. Cell-autonomous ablation of SNAP47 disrupts the layer-specific branching of callosal axons of projection cortical neurons *in vivo*, and this phenotype is recapitulated by ablation of BDNF or its receptor, TrkB. Our results provide insights into the molecular mechanisms of protein secretion, and they define the functions of SNAREs in BDNF signaling and regulation of neuronal connectivity.

INTRODUCTION

Neurons activated during experience may nearly simultaneously release fast neurotransmitters and diffusible polypeptides from distinct membrane-trafficking organelles. Synaptic neurotransmitter vesicles (SVs) reside at axon terminals and undergo exocytosis at highly compartmentalized active zones, whereas peptidergic vesicles are broadly distributed in axons and dendrites (Dean et al., 2012; Südhof, 2013). The core presynaptic release machinery includes SNAREs, synaptobrevin/VAMP2 (Syb2), SNAP25, and syntaxin1, whose assembly into ternary complexes primes SVs for rapid exocy-

tosis and overcomes the energy barrier for their fusion with the plasma membrane (Schoch et al., 2001; Südhof and Rothman, 2009; Wojcik and Brose, 2007). These SNAREs play similar roles in the release of catecholamines from dense core vesicles (DCVs) in chromaffin cells and promote membrane fusion *in vitro* (Giraudo et al., 2009; Sakaba et al., 2005; Sørensen et al., 2003b), which supports the hypothesis that SNAREs universally control secretion. Surprisingly, the contribution of SNAREs to secretion of neuronal proteins is largely unexplored. Moreover, invertebrate and vertebrate genomes have relatively few VAMPs and SNAPs, which raises the following question: to what extent are individual SNARE isoforms shared in a given neuron between organelles with different content?

These gaps in knowledge of the basic aspects of membrane trafficking present a challenge for understanding the mechanisms of experience-dependent plasticity at molecular and circuit levels. For example, experimental evidence suggests that both neurotransmitters and peptides may influence axon branching and patterning of synaptic networks of various neuron classes (Bloodgood et al., 2013; Cao et al., 2007; Cheng et al., 2011; Kerschensteiner et al., 2009; Pieraut et al., 2014; Wang et al., 2007; Yu et al., 2004). Yet, virtually all contemporary methods for pharmacological, genetic, or optogenetic control of network activity in live animals likely affect secretion in a non-selective manner, making it difficult to define the impacts of specific cues on neural circuit structure, function, and, ultimately, animal behavior. Likewise, cleavage of Syb2 with genetically encoded tetanus toxin (TeNT) has become a popular approach for blocking exocytosis of SVs (Kerschensteiner et al., 2009; Pieraut et al., 2014; Wang et al., 2007; Yu et al., 2004), but it remains unclear how TeNT affects other vesicle types. Although these problems can be partially overcome by ablating neurotransmitter or peptide-specific receptors, such strategies have a limited use for the identification of cellular sources of release.

The brain-derived neurotrophic factor (BDNF) has emerged as one of the key diffusible signals that is essential for axon growth, synaptogenesis, remodeling of mature synapses, learning, and memory (Lu et al., 2013; Park and Poo, 2013).

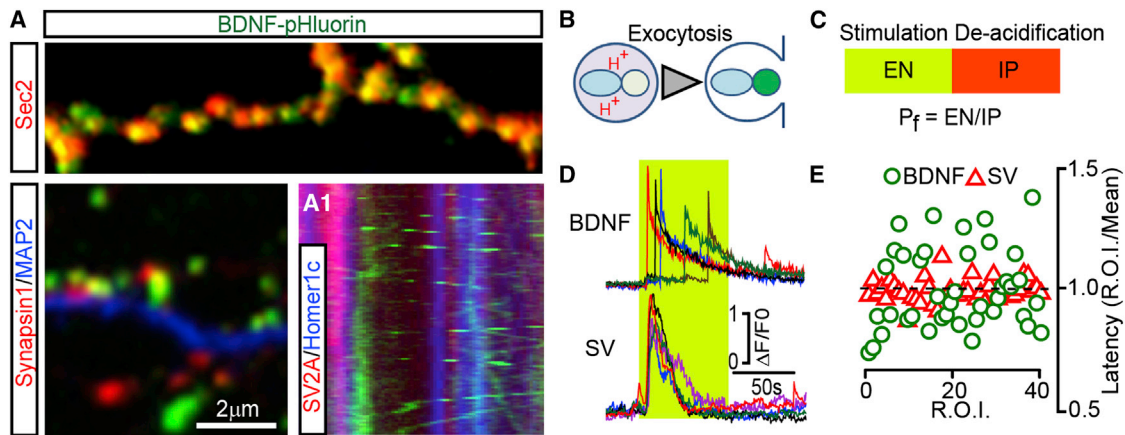

Figure 1. Intracellular Trafficking and Exocytosis of BDNF Vesicles

(A) DIV15 neurons expressing BDNF-pHluorin from a lentivirus were labeled with antibodies to GFP (as a probe for BDNF construct) and markers of either peptidergic (Sec2, top) or neurotransmitter vesicles (Synapsin1, bottom left). MAP2 labels dendrites. (Bottom right) Kymograph from time-lapse imaging of live neurons co-expressing BDNF-GFP and reporters of presynaptic terminals and dendritic spines, tdTomato-SV2A and EBFP2-Homer1c. See also [Figures S1 and S2](#). (B) Schematic shows reporter de-acidification during vesicle fusion with the plasma membrane. (C) A protocol for quantitative analysis of exocytosis. (D and E) Exocytosis of BDNF and SVs was monitored at DIV15 by time-lapse TIRF imaging of BDNF-pHluorin and SyP-pHluorin, respectively. (D) Sample traces reflecting fusion in different sites of the same neuron during direct depolarization with KCl (50 mM). Green box marks the time course of intracellular calcium rise, as determined in identical experimental settings in neurons expressing GCaMP3. (E) Latencies of isolated fusion events are plotted as ratios to averaged latency per cell ($n = 4$, 10 sites/neuron). See also [Figure S2](#), [Movies S1](#), [S2](#), [S3](#), and [S4](#), and [Supplemental Experimental Procedures](#).

While secretion of native neurotrophins is notoriously difficult to detect in real time, it is generally agreed that BDNF is transported by secretogranin2-positive vesicles that undergo exocytosis upon synaptic excitation and calcium influx ([de Wit et al., 2009](#); [Dean et al., 2012](#); [Dieni et al., 2012](#); [Kolarow et al., 2007](#); [Matsuda et al., 2009](#); [Sadakata et al., 2012, 2013](#)). Structurally, the axonal pool of these organelles resembles DCVs, whereas dendritic vesicles do not have characteristic dense cores ([Dieni et al., 2012](#); [Miyazaki et al., 2011](#)). Unlike SVs and chromaffin DCVs whose exocytosis is triggered by calcium binding to synaptotagmins 1, 2, and 9 ([Fernández-Chacón et al., 2001](#); [Geppert et al., 1994](#); [Maximov and Südhof, 2005](#); [Sørensen et al., 2003a](#); [Xu et al., 2007](#)), BDNF vesicles are believed to recruit calcium sensors CAPS and to be negatively regulated by Syt4, a synaptotagmin isoform that lacks calcium-binding activity in vertebrates ([Dai et al., 2004](#); [Dean et al., 2009](#); [Sadakata et al., 2012](#)). We found that, in spite of their remarkable differences with SVs, BDNF vesicles employ Syb2 and SNAP25 for fusion in all subcellular domains of cortical neurons. Our results imply that Syb2 and SNAP25 broadly regulate neuronal secretion and offer an alternative interpretation of previously described phenomena associated with disruption of these SNAREs in the brain. Nevertheless, release of BDNF also is controlled by SNAP47, a SNAP isoform that associates with Syb2 and SNAP25 but does not contribute to exocytosis and recycling of SVs. Cell-autonomous loss of SNAP47 impairs the layer-specific branching of callosal axons of pyramidal neurons in the somato-sensory cortex in vivo, suggesting that differentiation of cortical axons depends on autocrine BDNF/TrkB signaling rather than glutamatergic outputs onto postsynaptic targets.

RESULTS

Spatial and Temporal Dynamics of BDNF Exocytosis

To investigate the molecular mechanisms of BDNF secretion, we infected cortical neurons in primary cultures with a lentivirus encoding BDNF-pHluorin, a reporter comprised of full-length (pro) BDNF and a pH-sensitive form of GFP ([Matsuda et al., 2009](#)). The rationale for this approach and various controls that validate the appropriate post-translational modification, trafficking, and biological activity of BDNF fusion proteins are described in the accompanying [Supplemental Experimental Procedures](#). Confirming earlier studies ([Dean et al., 2012](#); [Matsuda et al., 2009](#); [Miyazaki et al., 2011](#)), immunofluorescence and live time-lapse imaging showed that BDNF vesicles were scattered in processes of mature neurons; contained another secreted peptide, secretogranin2; and were largely segregated from SVs. Unlike SVs, these organelles were not anchored at synapses, and they underwent bi-directional transport in axonal and dendritic shafts ([Figure 1A](#); [Figure S1](#)).

We then monitored the release of BDNF-pHluorin in live neurons using total internal reflection fluorescent (TIRF) time-lapse microscopy. Under these conditions, the reporter is barely detectable in intracellular vesicles due to their low luminal pH. During exocytosis, de-acidification leads to a rapid increase in fluorescence followed by a decay due to diffusion of cargo into the extracellular medium ([Figure 1B](#)). As shown previously ([Balkowiec and Katz, 2000](#); [Matsuda et al., 2009](#)), secretion of BDNF could be reliably induced by direct membrane depolarization with KCl, high-frequency bursts of action potentials triggered by electrical stimulation, or pharmacological augmentation of network activity with the GABA receptor blocker

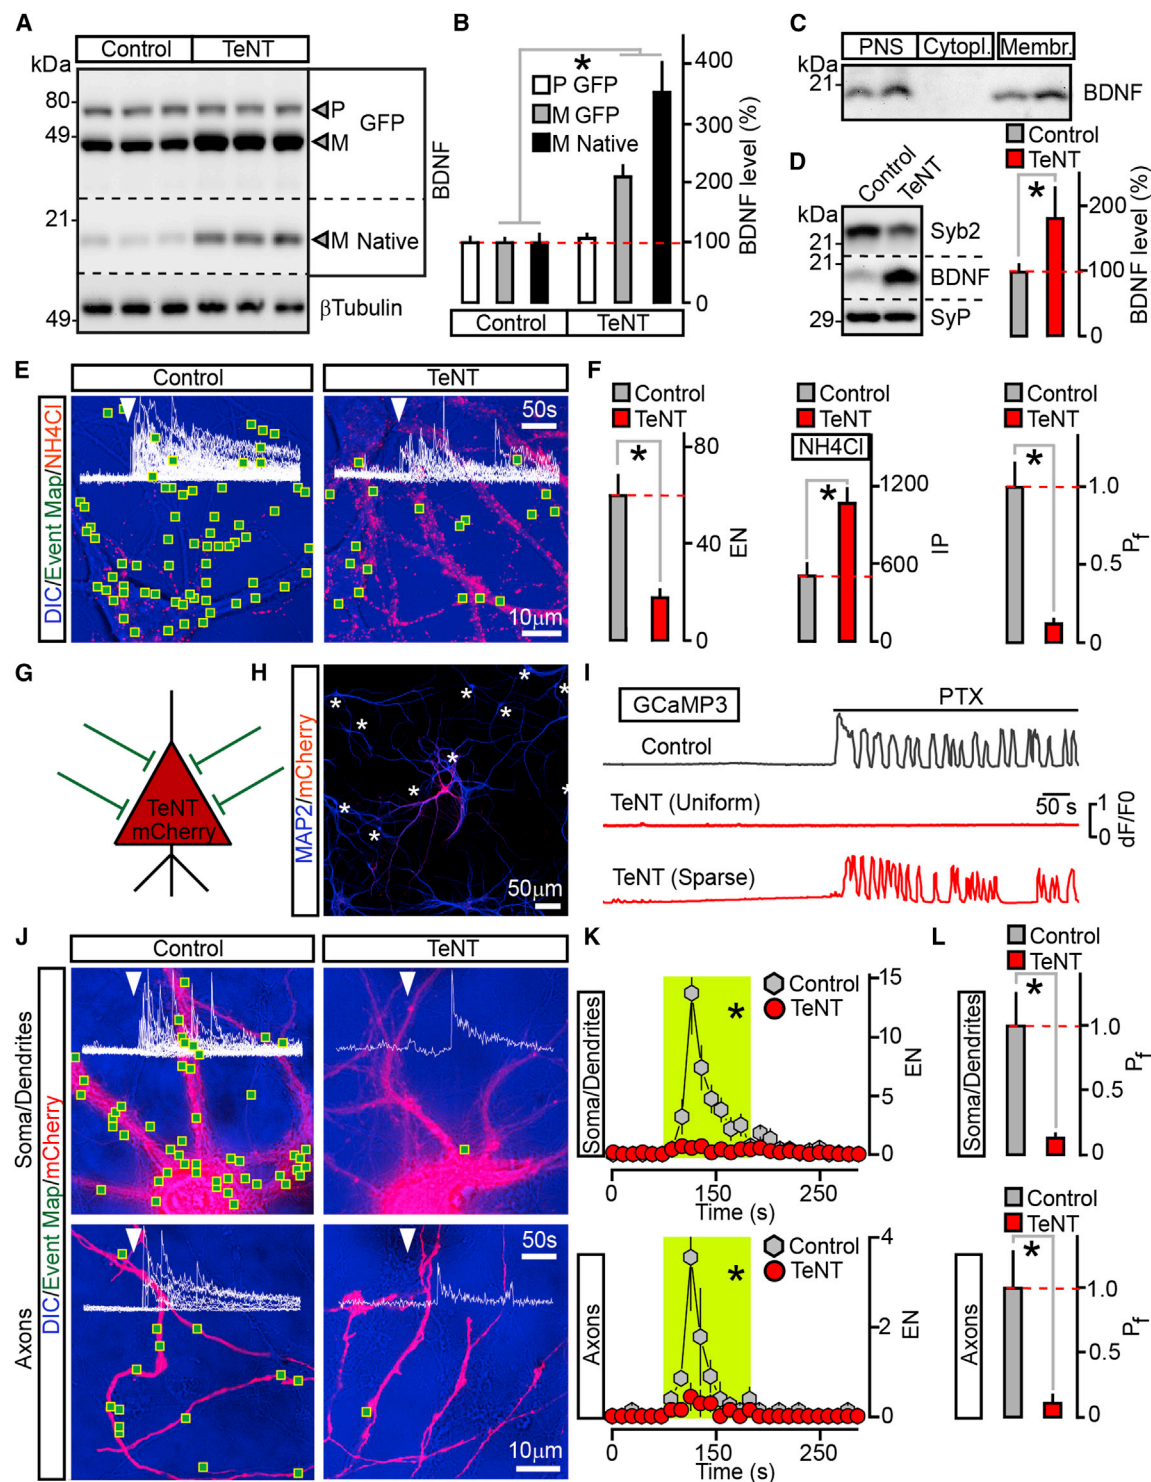

Figure 2. Analysis of BDNF Release in Neurons Carrying TeNT

(A and B) Measurements of pro (P) and mature (M) BDNF levels in cultured neurons that uniformly expressed BDNF-pHluorin alone (Control) or with TeNT. Quantitative immunoblotting was performed with an antibody to BDNF that recognizes all native and recombinant forms. β Tubulin was used as a loading standard. Representative blots and averaged values from three experiments are shown.

(C) Subcellular fractions of mouse forebrains were isolated by differential centrifugation and probed by immunoblotting for native BDNF. PNS, post-nuclear supernatant.

(legend continued on next page)

picrotoxin (PTX) (Figures S2A–S2D; Movie S1). To assess the efficacy of exocytosis, we measured three parameters: (1) number of isolated fusion events that occurred during fixed time intervals (EN) (we confirmed that these events reflected release by applying a membrane-impermeable hydrophilic quencher, bromophenol blue [Harata et al., 2006]); (2) number of internal vesicles (intracellular pool [IP]) in which BDNF-pHluorin could be detected following artificial de-acidification of lumens with ammonium chloride; and (3) probability of fusion (P_f) = EN/IP ratio. This value was calculated to account for variability in the integrated area of plasma membrane and/or density of available vesicles across independent imaging sessions (Figure 1C; Figures S2E and S2F). EN and P_f were diminished when stimulation was performed in the absence of extracellular calcium or in the presence of inhibitors of calcium channels known to be required for the secretion of native BDNF (Balkowiec and Katz, 2000; Figure S2G).

SVs are clustered at presynaptic terminals where they form readily releasable pools (RRPs) adjacent to active zones. These pools are primed by SNARE complex assembly for rapid synchronous exocytosis in response to action potential-dependent calcium influx (Südhof, 2013). By contrast, side-by-side comparison of neurons carrying BDNF-pHluorin or a reporter of SVs, synaptophysin (SyP)-pHluorin (Peng et al., 2012), indicated that secretion of BDNF is asynchronous (Figures 1D and 1E). The kinetics of BDNF release also drastically differed from transferrin receptor-positive recycling endosomes (Figures S2H–S2J). Moreover, only a fraction of BDNF vesicles fused at synapses regardless of stimulation type, as evidenced by simultaneous TIRF imaging of BDNF-pHluorin and genetically encoded pre- and postsynaptic markers, tdTomato-SV2A and EBFP2-Homer1c (Figures S2K–S2N). These results indicate that no primed vesicle pools exist that supply a synaptic or extra synaptic RRP equivalent to BDNF in cortical neurons.

Secretion of BDNF Is Directly Controlled by TeNT-Sensitive SNAREs

To explore the possibility that release of neurotransmitters and BDNF is driven by distinct SNARE complexes, we first evaluated the effects of TeNT, a protease that potently blocks the fusion of SVs by cleaving the vesicular SNARE, Syb2 (Schoch et al., 2001;

Yamasaki et al., 1994). Although the extracellular application of recombinant TeNT polypeptide previously has been shown to interfere with the release of BDNF in hippocampal cultures (Matsuda et al., 2009), it is unclear if this effect was direct. Indeed, TeNT-dependent loss of glutamatergic neurotransmission (Kerschenshneider et al., 2009; Pieraut et al., 2014; Yu et al., 2004; Zhang et al., 2008) may ultimately prevent the secretion of cargo from other membrane organelles whose exocytosis is coupled with synaptic excitation (Balkowiec and Katz, 2002; de Wit et al., 2009; Dean et al., 2012). We therefore investigated the effects of genetically encoded TeNT that was expressed under the control of the synapsin promoter, either globally or in a cell-autonomous manner, in only a small fraction of synaptically connected neurons. Similar approaches were used for all subsequent analyses of individual SNAREs described below.

Quantitative immunoblotting showed a strong increase in the levels of native BDNF and BDNF-pHluorin in cultured neurons that were uniformly infected with the TeNT lentivirus (Figures 2A and 2B). We also detected an accumulation of endogenous BDNF in membrane fractions isolated from the cortices of conditional mouse mutants that harbored TeNT in glutamatergic neurons in the postnatal forebrain (Pieraut et al., 2014; Figures 2C and 2D). TIRF microscopy revealed that TeNT prevented the release of BDNF-pHluorin from cultured neurons resulting in its intra-vesicular retention during stimulation with KCl (Figures 2E and 2F). Conventional imaging of the entire vesicle pool suggested that TeNT interferes with exocytosis rather than transport from the ER to the Golgi, budding from the Golgi, and endosomal trafficking (Figures S3A–S3C).

Because release of BDNF is regulated by synaptic network activity, we next tested if TeNT-sensitive SNAREs promote the secretion in a cell-autonomous manner. To accomplish this task, BDNF-pHluorin, TeNT, and a red tracer (mCherry) were sparsely co-expressed in ~5% of cortical neurons in culture (Figures 2G and 2H; Figure S3D–S3F). Infected neurons received intact glutamatergic inputs from surrounding wild-type cells, as demonstrated by GCaMP-based imaging of calcium signals elicited by the application of PTX (Figure 2I; Figures S3G and S3H). These experimental settings allowed us to bypass the effects of the protease on exocytosis of SVs and to monitor the fusion of BDNF vesicles in distinct subcellular

(D) Quantitative immunoblot measurements of mature BDNF levels in membrane fractions prepared from cortices of wild-type P15 mice (Control) and their littermates carrying TeNT in glutamatergic neurons (*CamKII α :Cre/R26^{flloxstopTeNT}*) (n = 5 mice/genotype). The reduction of Syb2 band intensity is due to cleavage by TeNT, which makes Syb2 undetectable with antibodies.

(E and F) TIRF microscopy analysis of vesicle exocytosis in DIV15 cultured neurons that globally expressed BDNF-pHluorin without or with TeNT. (E) Pseudo-colored differential interference contrast (DIC) images with superimposed maps of all sites where vesicle fusion was detected during transient depolarization with KCl (2 min). Red puncta are intracellular reporter-positive vesicles visualized by perfusing 50 mM NH₄Cl following stimulation. (F) Averaged EN (calculated for a 2-min window of stimulation in entire fields of view), IP, and P_f (n = 9/group).

(G–L) Cell-autonomous effects of TeNT on BDNF release. Neurons were sparsely infected (~5% of the total population) with lentiviruses encoding BDNF-pHluorin and mCherry alone or together with TeNT. These cells received synaptic inputs from wild-type neurons, as depicted in (G). (H) An example of infection pattern is shown. Cultures were stained for MAP2. Asterisks label somas of reporter-negative cells. (I) PTX-induced (100 μ M) calcium signals were recorded from neurons co-expressing TeNT, mCherry, and GCaMP3, either globally or sparsely, as described above. (J–L) Exocytosis of BDNF vesicles was monitored by TIRF microscopy at DIV15. (J) DIC and mCherry images show mapped regions of somato-dendritic and axonal domains where vesicle fusion was observed during 2-min depolarization with KCl. Superimposed traces of BDNF-pHluorin fluorescence sampled in time-lapse mode (inserts, arrows mark times of excitation) reflect exocytosis in each site. (K) Averaged EN in different subcellular compartments of individual neurons, plotted as a function of time (10-s bin). Green boxes mark the window of transient excitation. (L) Mean P_f of evoked fusion in somas, dendrites, and axons (n = 7–8/group).

Quantifications are represented as mean \pm SEM; n corresponds to numbers of trials performed with at least three independent culture preparations; *p < 0.001 (Student's t test).

domains of single neurons (Movies S2 and S3). TeNT abolished secretion in this case as well, even when cultures were depolarized continuously. Remarkably, quantifications of EN and P_f demonstrated that exocytosis was uniformly and nearly completely blocked in cell bodies, dendrites, and axons (Figures 2J–2L).

Exocytosis of BDNF Is Driven by the Vesicular SNARE Syb2

At least nine genes encoding vesicular SNAREs are expressed in the mammalian brain, including seven different Syb/VAMPs, YKT6, and Sec22b (Figure 3A, based on Allen Brain Atlas database). We systematically examined the sensitivity of these SNAREs to TeNT by immunoblotting following the overexpression of cDNAs in HEK293 cells. Confirming earlier experiments with Sybs/VAMPs 1–3 (McMahon et al., 1993; Yamasaki et al., 1994), these proteins were cleaved in the presence of the protease whereas the remaining isoforms were resistant (Figure 3B). We then designed small hairpin RNAs (shRNAs) that disrupt the expression of native TeNT-sensitive Syb/VAMPs, and we studied the outcomes of knockdowns (KDs) on neuronal secretion of BDNF using a combination of biochemical and TIRF imaging readouts. We initially introduced pairs of lentiviruses driving hairpins under the control of H1 promoter to target two non-overlapping coding regions of each Syb/VAMP transcript. Single shRNAs from a mix that produces a phenotype were then tested in isolation or co-expressed with the rescue shRNA-resistant cDNA from a dual H1/Synapsin-promoter lentivirus vector (Figure S4A; Table S1). The potencies and specificities of these hairpins were confirmed by immunohistochemistry and immunoblotting with relevant antibodies (Figures S4D–S4F; data not shown).

Loss of Syb2 alone fully recapitulated the effects of TeNT. KD of this SNARE in all neurons in culture resulted in an accumulation of mature BDNF forms and inhibited the depolarization-dependent exocytosis of BDNF-pHluorin without altering the subcellular localization of intracellular vesicles. In contrast, KDs of two other TeNT substrates, Syb1 and Syb3, failed to significantly affect the BDNF levels, EN, and P_f (Figures 3C–3F; Figures S3C, S4B, and S4C). TIRF imaging of BDNF-pHluorin in sparsely infected cultures demonstrated that, similar to TeNT, KD of Syb2 blocks the exocytosis in a cell-autonomous manner and in all subcellular domains. Single mCherry-tagged neurons carrying a Syb2-directed shRNA had a strong reduction of both the frequency of evoked fusion events and P_f across somas, dendrites, and axons, despite receiving excitatory inputs from wild-type cells. These defects were rescued by the Syb2 cDNA containing silent mutations in the shRNA target site, hence ruling out off-target artifacts (Figures 3G–3I; Figure S4G). Also, native Syb2 could be detected in a significant fraction of BDNF vesicles by immunofluorescence microscopy, indicating that these organelles recruit Syb2 (Figures S4H–S4J).

Secretion of BDNF Is Regulated by Two Membrane SNAPs

Our results imply that Syb2 directly promotes the release of BDNF independently of its presynaptic function and, surprisingly, does so in axons, dendrites, and somas. To test if this pre-

viously unappreciated function of Syb2 involves interactions with unique vesicle-specific effectors on the plasma membrane, we focused on members of the membrane SNAP protein family with abundant expression in the brain, SNAPs 23, 25, 29, and 47 (Figure 4A; based on Allen Brain Atlas database; Holt et al., 2006; Johansson et al., 2008; Su et al., 2001; Suh et al., 2010). Imaging of cortical cultures that broadly expressed SNAP-specific hairpins demonstrated that exocytosis of BDNF-pHluorin was suppressed after the ablation of SNAP25 and SNAP47 (Figures 4B–4D). However, only KD of SNAP25 resulted in an accumulation of bulk intracellular BDNF under these conditions, indirectly suggesting that SNAP47 has a modulatory and/or spatially restricted function (Figures S5A and S5B).

Previous *in vitro* studies have shown that SNAP47 is unable to fully substitute for SNAP25 in fusion of liposomes driven by SNARE complexes containing Syb2 and Syntaxin1 (Holt et al., 2006). SNAP47 also has been implicated in hippocampal long-term potentiation (LTP) (Jurado et al., 2013), yet its role in secretion has remained unclear. The involvement of SNAP47 in exocytosis of BDNF vesicles is intriguing, since induction of Hebbian plasticity critically depends on BDNF signaling (Kang and Schuman, 1995; Park and Poo, 2013; Patterson et al., 1996). To gain more insight into functions of two SNAP isoforms in BDNF trafficking, we examined the cell-autonomous outcomes of their KDs on exocytosis of BDNF-pHluorin in single sparsely infected neurons. KD of SNAP25 uniformly abolished the depolarization-induced release in all subcellular domains. On the contrary, SNAP47-deficient cells only exhibited a prominent loss of exocytosis in axons, albeit we also detected a shift in kinetics of vesicle fusion across their entire surface (Figures 4E–4J; Figure S6). Consistent with these notions, both SNAP isoforms were distributed throughout neuronal processes (Figures S5F–S5H). The phenotypes associated with each KD could be reversed by corresponding shRNA-insensitive cDNAs (Figures 4E–4J; Figures S5A–S5E and S6). Neither KD altered the distribution of internal BDNF vesicles, making it unlikely that secretion was disrupted due to abnormal intracellular trafficking (Figure S3C). To test whether SNAP47 and SNAP25 interact with each other, we immunoprecipitated these SNAREs with isoform-specific antibodies from mouse brain extracts. Immunoblotting showed that SNAP47 and SNAP25 are abundant in complexes that contain Syb2 and syntaxin1 (Figure 4K).

To mimic activity-dependent secretion using a more physiologically relevant paradigm, we also induced exocytosis with bursts of action potentials. Cortical cultures were sparsely infected with BDNF-pHluorin and mCherry, and axonal secretion was monitored before, during, and after 30-s stimulus trains that were triggered at various frequencies by brief injection of current through an extracellular electrode. Fusion events were detectable, yet, relatively rare at 10 Hz, whereas 100-Hz trains elicited robust responses. Nevertheless, TeNT or KD of SNAP47 potently suppressed EN and P_f at both frequencies (Figures 5A–5D).

SNAP47-Deficient Neurons Have Normal Exocytosis and Recycling of SVs

Our experiments reveal largely promiscuous roles of Syb2 and SNAP25 in membrane fusion and identify SNAP47 as a critical

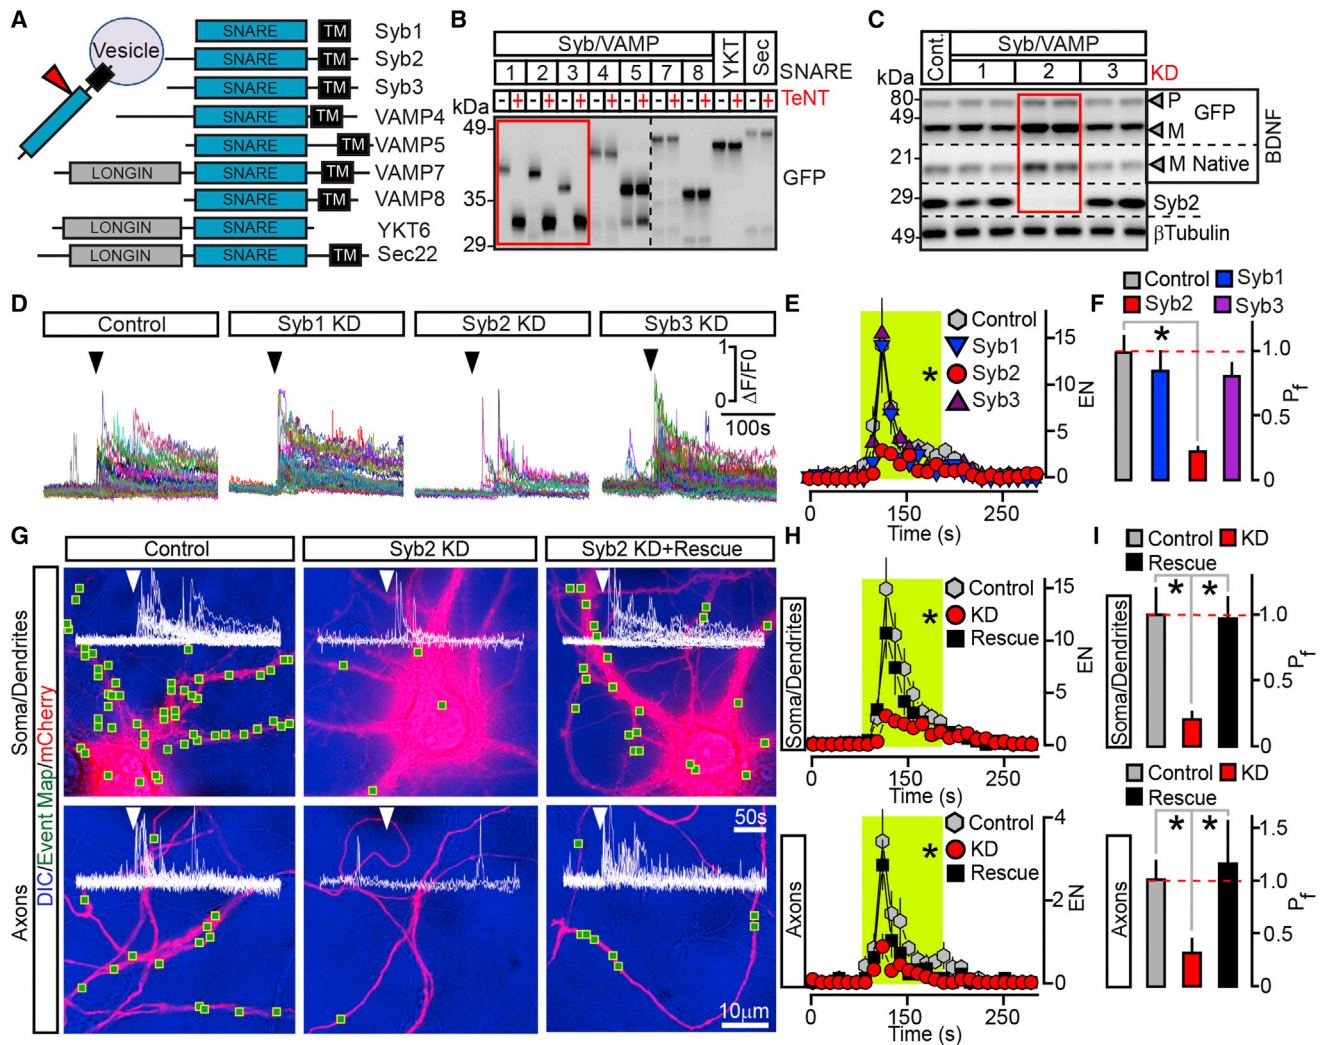

Figure 3. Syb2 Drives the Exocytosis of BDNF Vesicles in Axons and Dendrites Independently from Its Presynaptic Function

(A) Domain structures of vesicular SNAREs. (B) Biochemical assessment of SNARE sensitivity to TeNT. Homogenates of HEK293 cells expressing different GFP-tagged SNAREs alone or together with TeNT were probed by immunoblotting for GFP. Dashed line indicates splicing of two different gels. (C–F) Cortical cultures were broadly co-infected at DIV5 with lentiviruses expressing BDNF-pHluorin and two shRNAs that target non-overlapping sequences of specific TeNT-sensitive Syb/VAMPs (KD). All experiments were performed at DIV15. (C) Immunoblot analysis of pro- (P) and mature (M) BDNF levels was performed using antibodies to BDNF and β Tubulin, as a loading standard ($n = 6$ control and Syb/VAMP-deficient cultures, examined in duplicates). Quantifications are shown in Figure S4B. (D) TIRF traces represent all events of depolarization-induced vesicle fusion detected in isolated sites of control and Syb1–3-deficient neurons. Arrows mark times of excitation. (E) Averaged EN, plotted as a function of time. Green box marks the window of transient excitation. (F) Mean P_f across the cell bodies and processes is shown. Control, $n = 7$; Syb1 KD, $n = 6$; Syb2 KD, $n = 7$; Syb3 KD, $n = 7$; * $p < 0.05$ (ANOVA). (G–I) Syb2 directly mediates BDNF release in all subcellular domains. Exocytosis was monitored by TIRF microscopy in somas, dendrites, and axons of isolated neurons in DIV15 cultures that were sparsely co-infected with viruses encoding BDNF-pHluorin, mCherry, and Syb2 shRNA without or with shRNA-resistant rescue cDNA. (G) DIC and mCherry images show mapped regions of somato-dendritic and axonal domains where fusion was observed during transient depolarization. Superimposed traces of BDNF-pHluorin fluorescence reflect exocytosis in each site. (H) Averaged EN in different subcellular compartments, plotted as a function of time. regulator of vesicular release. To test if SNAP47 is necessary for exocytosis of SVs, we examined synapses of mature neurons in culture by confocal microscopy and electrophysiology. Uniform expression of TeNT or KD of Syb2, SNAP25, or SNAP47 did not disrupt the formation of glutamatergic and GABAergic terminals,

consistent with previous notions that vesicular exocytosis is not necessary for gross synaptic differentiation *in vitro* (Harms and Craig, 2005; Schoch et al., 2001; Figure S7; data not shown). We then performed whole-cell recordings to evaluate the properties of different synapse types. As expected, TeNT and

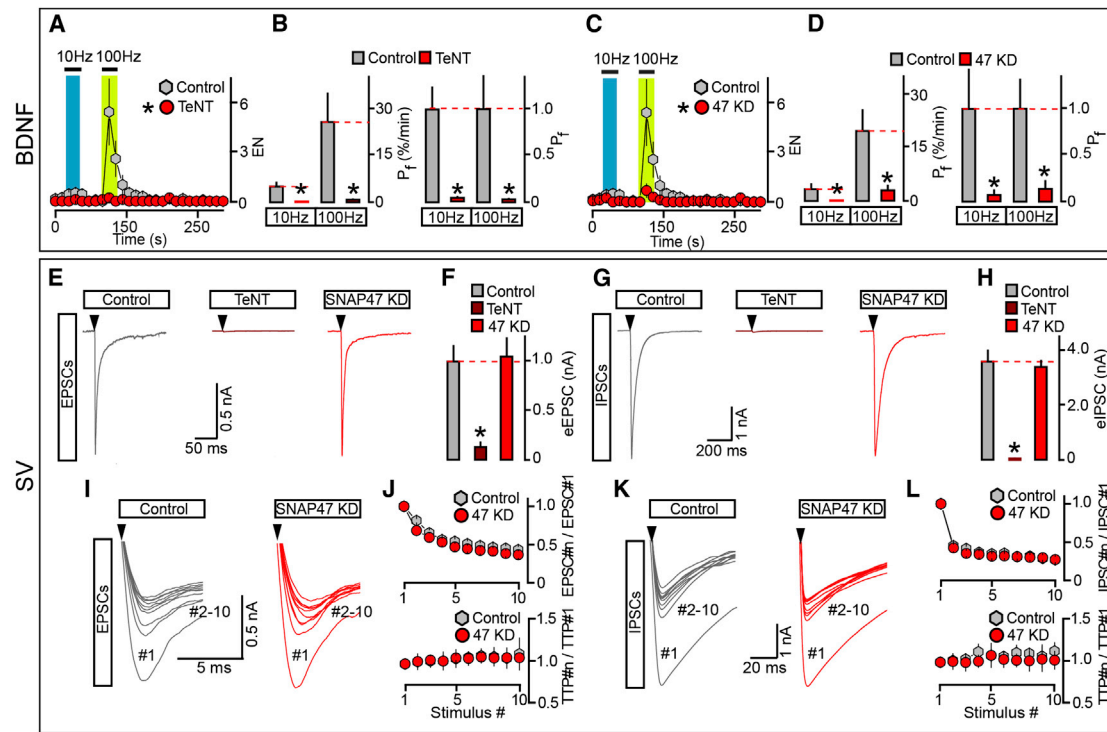

Figure 5. SNAP47 Promotes the Exocytosis of BDNF but Not Neurotransmitter Vesicles

(A–D) Frequency dependence of BDNF release in isolated wild-type and SNARE-deficient neurons. Cultures were sparsely infected with BDNF-pHluorin and mCherry lentiviruses alone or together with TeNT or shRNA against SNAP47 (KD). TIRF imaging was performed at DIV15. Exocytosis was elicited by electrical stimulation at 10 and 100 Hz (1 ms/10V/pulse) and monitored in mCherry-tagged axons. Each stimulus train was applied for 30 s. (A and B) Averaged EN and P_f . Colored boxes mark the times of action potential trains. P_f values are shown without normalization or as a fraction of control. Control, $n = 14$; TeNT, $n = 10$; * $p < 0.001$ (Student's t test). (C and D) EN and P_f were measured in control and SNAP47-deficient neurons and represented as described above. EN: Control, $n = 14$, this group is the same as for TeNT experiments; SNAP47 KD, $n = 16$. P_f : Control, $n = 16$; SNAP47 KD, $n = 19$. * $p < 0.001$ (ANOVA).

(E–L) Exocytosis of SVs in neurons carrying TeNT or shRNA against SNAP47. Cortical cultures were uniformly infected with corresponding lentiviruses. The eEPSCs and eIPSCs were sampled at DIV15 in whole-cell voltage clamp mode. The eEPSCs and eIPSCs were triggered by single-action potentials or 10-Hz stimulus trains, and were pharmacologically isolated by the addition of GABA or AMPA/NMDA receptor blockers. (E and F) Samples of individual eEPSCs (E) (scale bars apply to all traces and arrows mark times of action potentials) and averaged eEPSC amplitudes (F). Control, $n = 13$; TeNT, $n = 11$; SNAP47 KD, $n = 13$. * $p < 0.001$ (ANOVA). (G and H) Samples of single eIPSCs (G) and averaged eIPSC amplitudes (H). Control, $n = 19$; TeNT, $n = 3$; SNAP47 KD, $n = 14$. * $p < 0.001$ (ANOVA). (I–L) Short-term plasticity of excitatory and inhibitory synapses in wild-type and SNAP47-deficient neurons. (I and K) Onsets of aligned EPSCs (I) and IPSCs (K) that were elicited by 10-Hz trains of ten action potentials (arrows). (J and L) (Top) Averaged profiles of synchronous EPSC (J) and IPSC (L) depression during repetitive stimulation are presented as ratios of PSC amplitudes. (Bottom) Averaged profiles of EPSC (J) and IPSC (L) de-synchronization are plotted as ratios to times to peak (TTP). EPSCs: Control, $n = 12$; SNAP47 KD, $n = 8$. IPSCs: Control, $n = 16$; SNAP47 KD, $n = 12$.

Data are plotted as mean \pm SEM. See also Figure S7 and Table S2.

hairpins against Syb2 and SNAP25 diminished the amplitudes of evoked excitatory and inhibitory postsynaptic currents (eEPSCs and eIPSCs, respectively) and the rates of spontaneous SV fusion alike. However, synaptic strength was unaltered in neurons lacking SNAP47, despite their defects in exocytosis of BDNF (Figures 5E–5H; Table S2). In addition, wild-type and

SNAP47-deficient neurons had indistinguishable profiles of PSC depression and de-synchronization during action potential trains as well as kinetics of quantal AMPA- and GABA-type currents (Figures 5I–5L; Table S2; data not shown). Hence, unlike Syb2 and SNAP25, SNAP47 appears to be unnecessary for SV exocytosis and recycling.

Aligned DIC and mCherry images show mapped sites of depolarization-induced fusion, actual events of exocytosis in each site, EN plotted as a function of time, and P_f ($n = 9$ –11/group). (E–G) Examples of exocytosis, averaged EN, and P_f in different subcellular compartments of control and SNAP25-deficient neurons are shown. * $p < 0.01$ (ANOVA). (H–J) Examples of exocytosis, mean EN, and P_f in SNAP47-deficient neurons. * $p < 0.05$ (ANOVA). Control groups apply to both SNAP isoforms. Quantifications are represented as mean \pm SEM. See also Figures S5 and S6.

(K) Solubilized proteins were co-immunoprecipitated (IP) from mouse forebrain extracts with control antibody (Ig) or antibodies against SNAP25 (top) or SNAP47 (bottom). Attached complexes were examined by immunoblotting with antibodies to SNAP25, SNAP47, Syb2, and Syntaxin1. Equal amounts of total protein were applied to each lane.

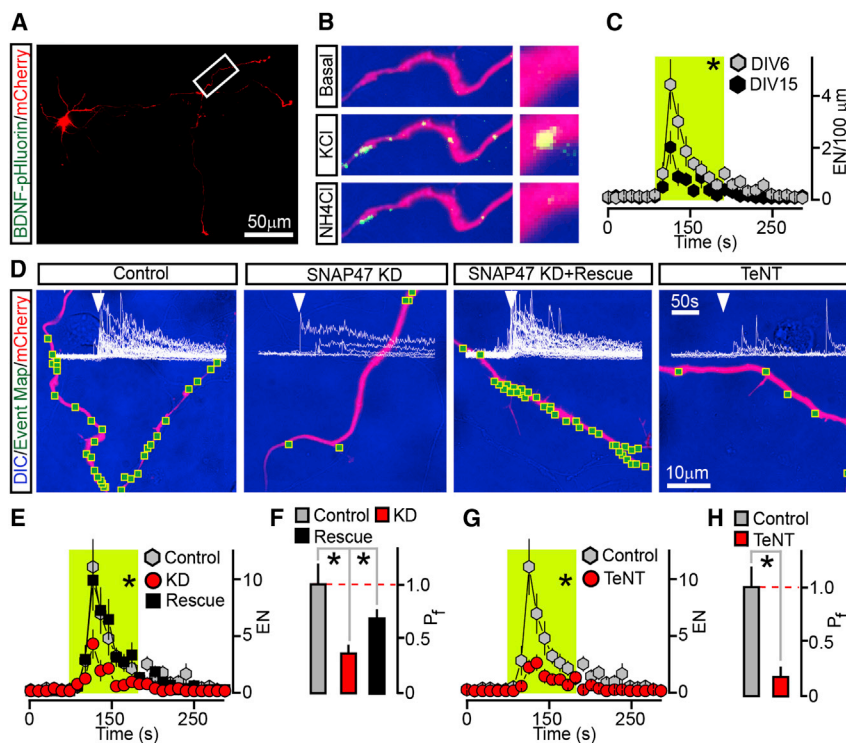

Figure 6. Analysis of BDNF Release in Differentiating Axons

Cultured cortical neurons were sparsely co-infected at DIV0 with BDNF-pHluorin and mCherry lentiviruses alone (Control) or together with viruses encoding TeNT or shRNA against SNAP47 (without or with rescue cDNA). Axonal exocytosis was monitored by TIRF microscopy at DIV6.

(A) Typical low-magnification image shows axons of a neuron tagged with mCherry.

(B) Examples of BDNF-pHluorin fluorescence in a distal fragment of an axon under the normal conditions (Basal) during depolarization with KCl and after vesicle de-acidification with NH_4Cl .

(C) Averaged EN in axons of mature (DIV15) and differentiating (DIV6) wild-type neurons were normalized to axon length and plotted as a function of time. DIV6, $n = 10$; DIV15, $n = 7$.

(D) DIC and mCherry images show mapped sites of depolarization-induced fusion and actual BDNF-pHluorin responses detected in each site of control, SNAP47-deficient, and TeNT-expressing neurons. (E–H) Averaged EN and P_t . * $p < 0.02$ (ANOVA). Note that, in this case, rescue is significant but incomplete, perhaps due to the short time course of cDNA overexpression.

See also Figures S8A and S8B.

SNAP47 Is Essential for Axon Differentiation In Vitro and In Vivo

Targeted disruption of vesicular release in animal brains is becoming increasingly popular for studies of the role of neuronal activity in regulation of connectivity. For instance, several laboratories have shown that inducible expression of genetically encoded TeNT interferes with wiring of olfactory sensory neurons, photoreceptors, pyramidal neurons, and inhibitory GABAergic interneurons in the cerebral cortex and hippocampus (Kerschensteiner et al., 2009; Pieraut et al., 2014; Wang et al., 2007; Yu et al., 2004). While these phenomena are widely believed to reflect the instructive role of excitatory synaptic outputs, the involvement of BDNF or other secreted peptides cannot be ruled out. Indeed, BDNF is known to be necessary for axon growth and branching (Cao et al., 2007; Cheng et al., 2011; Marshak et al., 2007; Park and Poo, 2013), and we found that, by cleaving Syb2, TeNT directly blocks the release of fast neurotransmitters and BDNF. Notably, Syb2, SNAP25, and SNAP47 are expressed in the developing brain prior to the onset of synaptogenesis, with SNAP47 turning on as early as embryonic day 10 (Holt et al., 2006). We therefore monitored secretion of BDNF in axons of differentiating SNAP47-deficient cortical neurons, and we examined axon morphologies in culture and in the mouse brain in vivo. As demonstrated above, this strategy enabled us to interfere with axonal exocytosis of BDNF without affecting SVs. We initially imaged BDNF-pHluorin in isolated mCherry-tagged neurons in dissociated cultures. These cells were sparsely infected with viruses immediately after plating and analyzed 6 days later, when a marker of presynaptic boutons, synapsin1, remained diffusely distributed in axons. Immunostaining confirmed that

endogenous SNAP47 and other SNAREs were present in axons at this stage (Figures S8A and S8B). Differentiating neurons displayed robust exocytosis of BDNF-pHluorin during membrane depolarization (Figures 6A–6C; Movie S4). Secretion was blocked by TeNT or KD of SNAP47, but was restored in the presence of rescue SNAP47 cDNA (Figures 6D–6H).

To determine how axonal exocytosis of BDNF impacts axon differentiation, a mix of two plasmids encoding a monomeric form of Venus and shRNA directed against SNAP47 was unilaterally introduced into the somatosensory cortex of E15.5 mouse embryos via electroporation (Courchet et al., 2013). This method allows for selective targeting of callosally projecting pyramidal neurons that populate the superficial layers 2/3. As the first step, the outcomes of SNAP47 KD in layer 2/3 neurons on their axon morphologies were assessed in cultures prepared from the cortices of electroporated embryos. SNAP47-deficient neurons (~1% of the entire pool, as determined by mVenus imaging, data not shown) had a slightly increased total axon length, but exhibited a significant reduction in the number of terminal branches. The branching defect could be reversed with shRNA-resistant SNAP47 cDNA or by continuous incubation with recombinant BDNF added in the culture medium (Figures 7A and 7B).

We then investigated the SNAP47 function in vivo, by imaging coronal cortical sections from mice that were electroporated at E15.5 and sacrificed at postnatal day 21 (P21). At P21, axons establish adult-like patterns of innervation in layers 2/3 and 5, both ipsi- and contralaterally (Courchet et al., 2013). On the contralateral side, the genetic manipulation was axon specific since neurons projected into the normal environment. Immunolabeling of sections isolated from wild-type animals showed

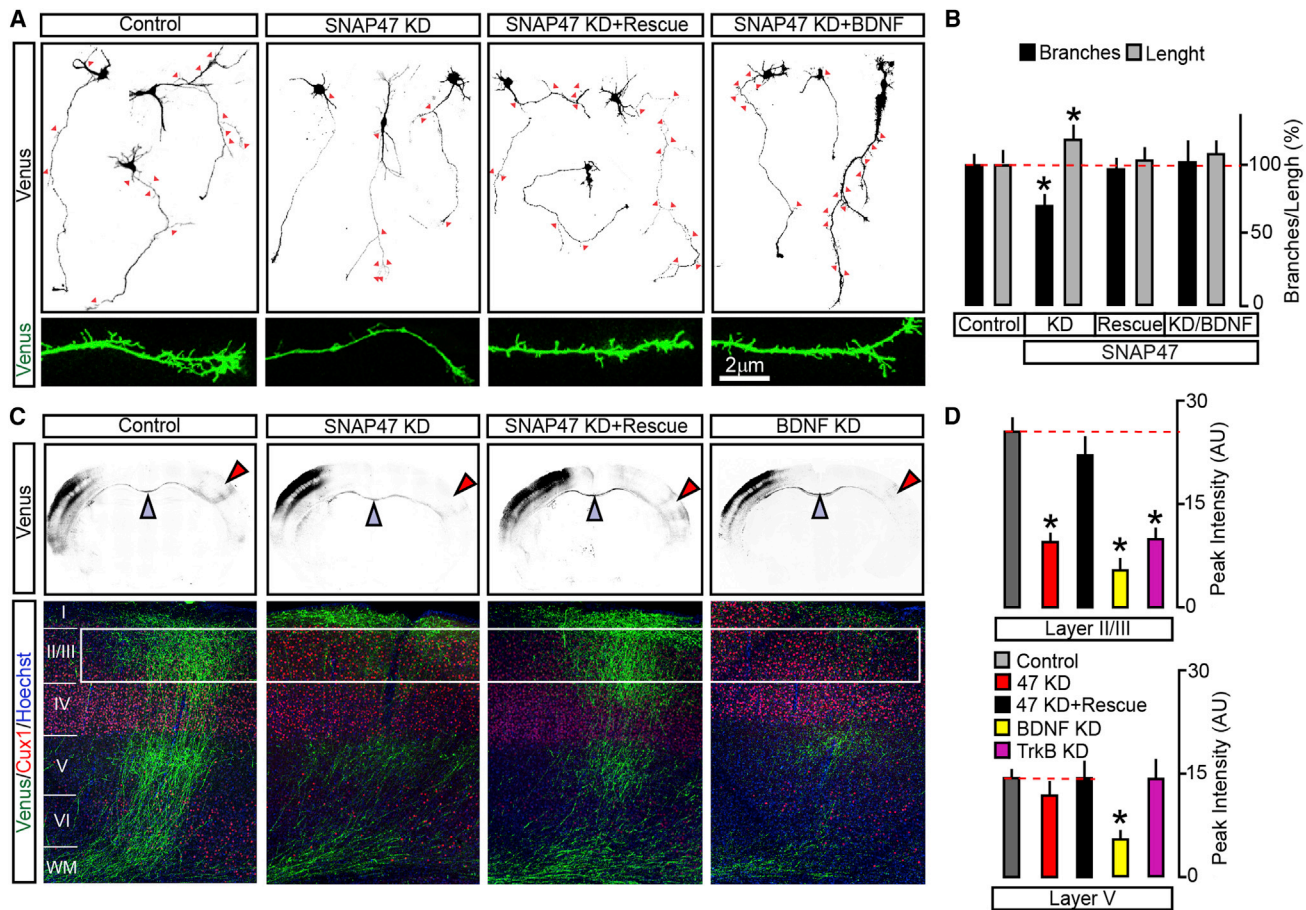

Figure 7. SNAP47 Is Essential for BDNF-Dependent Axon Branching In Vitro and In Vivo

(A and B) Cortices of E15.5 mouse embryos were electroporated ex vivo with the pSCV2-mVenus plasmid together with control shuttle vector or vectors driving the expression of SNAP47 shRNA alone or with rescue cDNA. Morphologies of differentiating mVenus-positive axons were then examined in primary cultures prepared from these mice. Axon identities were confirmed by immunostaining for SMI312 and MAP2 (not shown). (A) Typical images of DIV5 neurons carrying indicated constructs. Cultures were maintained in the normal medium or with the addition of recombinant BDNF (50 ng/ml, applied at DIV1). Arrows mark each axonal branch. (Bottom) Enlarged fragments of axons. (B) Quantifications show total axon length and branch numbers. Data from three independent cultures were normalized to control in each case. Control, $n = 62$ axons; SNAP47 KD, $n = 74$; SNAP47 KD + Rescue, $n = 51$; SNAP47 KD + BDNF, $n = 14$. * $p < 0.05$ (ANOVA).

(C and D) E15.5 embryos were in utero electroporated into one cortical hemisphere with mVenus tracer together with control shuttle vector or vectors encoding indicated shRNAs. Axon branching was examined by imaging of brain slices at P21. (C) (Top) Low-magnification images of coronal brain sections. mVenus signal is shown in black. Electroporated (ipsilateral) sides are on the left. Blue arrows mark corpus callosum. Red arrows point to contralateral branching. (Bottom) Confocal images of contralateral sides of cortical sections stained for mVenus, a layer-specific marker (Cux1), and a nuclear marker (Hoechst). (D) Average surface areas of mVenus fluorescence in layers 2/3 and 5 of contralateral cortex. Control, $n = 11$ mice; SNAP47 KD, $n = 8$ mice; SNAP47 KD + Rescue, $n = 5$ mice; BDNF KD, $n = 3$ mice; TrkB KD, $n = 8$ mice. * $p < 0.001$ (ANOVA). Data are plotted as mean \pm SEM. See also Figure S8.

that native SNAP47 was abundant in callosal axons (Figure S8C). Axons of mVenus-positive SNAP47-deficient neurons formed, grew, and successfully crossed the midline, but had a drastically reduced terminal arborization in the contralateral layers 2/3. Again, the defect of terminal branching was alleviated by co-expression of SNAP47 shRNA with shRNA-insensitive cDNA (Figures 7C and 7D). Nonetheless, KD of SNAP47 had no detectable effect on density of dendritic spines (Figures S8D and S8E), indicating that disruption of connectivity was likely restricted to axons. To ensure that these changes in callosal axon structure are attributable to abnormal BDNF signaling, we performed in utero electroporation with shRNAs against BDNF, or its receptor,

TrkB. The morphological defects of contralateral axons of BDNF- and TrkB-deficient layer 2/3 neurons were similar to SNAP47-deficient neurons, albeit KD of BDNF produced a more robust effect with significant attenuation of branching in layer 5 (Figures 7C and 7D; Figures S8F and S8G).

DISCUSSION

In summary, these studies elucidate the roles of SNAREs in vesicular exocytosis, BDNF secretion, and neural circuit development. A large body of work shows that Syb2 and SNAP25 are essential for calcium-induced release of neurotransmitters and

monoamines in central neurons and chromaffin cells, respectively (Sørensen et al., 2003b; Südhof, 2013; Südhof and Rothman, 2009). These SNAREs are thought to operate by priming vesicles and catalyzing fusion at specific sites, such as the pre-synaptic active zones. Remarkably, Syb2 and SNAP25 also trigger the release of BDNF from organelles that traffic and fuse with the plasma membrane across axons and dendrites, and do not form discrete pools that are primed for rapid exocytosis. By contrast, SNAP47 plays a more restricted role, perhaps as a part of a unique SNARE complex. SNAP47 interacts with SNAP25, promotes the exocytosis of BDNF in a cell-autonomous manner, but appears to be dispensable for synaptic release from SVs. Thus, two distinct types of neuronal vesicles share Syb2 and SNAP25, but their exocytosis is differentially controlled through combinatorial use of SNAREs.

Experiments with mutant animals carrying TeNT have led to a hypothesis that experience-driven refinement of connectivity is guided by neurotransmission between two relaying neurons in a given circuit (Okawa et al., 2014). Our findings challenge the generality of this model and underscore an alternative pathway that depends on autocrine BDNF/TrkB signaling. First, we show unambiguously that, by cleaving Syb2, TeNT abolishes the release of neurotransmitters and BDNF. We further demonstrate that cell-autonomous ablation of SNAP47, which evidently does not affect SVs, leads to defects in layer-specific branching of callosal axons that are similar to those caused by KD of BDNF or its receptor, TrkB, and those previously detected upon expression of TeNT in pyramidal neurons in the same cortical area (Wang et al., 2007). Neurotransmitters and peptides may impact axon and synapse development by binding to their receptors in spatially segregated micro-domains. Our results favor the scenario that axonally released BDNF promotes cortical axon branching via TrkB receptors localized on the same axon (Cao et al., 2007; Cheng et al., 2011).

Peptidergic vesicles contain diffusible cues other than BDNF (Lessmann et al., 2003), though their cargo may vary in different neuron classes and developmental stages. Identification of SNAREs essential for BDNF exocytosis will facilitate the further understanding of mechanisms of peptide secretion and will enable the design of new genetic tools to investigate the outcomes of secretion on neural circuit structure and information processing. In this regard, SNAP47 is a particularly attractive molecule due to its selectivity and unusually large size with putative sequences that may mediate protein-protein interactions (Holt et al., 2006). It would be of great interest to explore the interplay between this SNARE and other known and yet unidentified elements of membrane-trafficking machinery, including calcium sensors (Sadakata et al., 2012; Südhof, 2013) and scaffolds that may recruit organelles to release sites.

EXPERIMENTAL PROCEDURES

Neuronal Cultures

Cortices of P1 pups were dissociated by trypsin digestion; cells were plated on circle glass coverslips (Harvard Apparatus) coated with poly-D-Lysine (Sigma-Aldrich). Cultures were maintained for 4 days in MEM (Invitrogen) supplemented with fetal bovine serum (FBS), B-27 (Invitrogen), glucose, transferrin, and Ara-C (Sigma) followed by incubation in the serum-free medium. Neurons were seeded at 25,000–50,000 cells/cm² for imaging and electro-

physiological studies and at 150,000–175,000 cells/cm² for immunoblotting. In both preparations, the densities of astrocytes did not exceed 2%–3%, as determined by immunostaining for GFAP.

Virus Infection

Recombinant lentiviruses were produced by co-transfection of HEK 293T cells with corresponding shuttle vectors and pVSVg and pCMVΔ8.9 plasmids that encode the elements essential for packaging viral particles. Transfections were performed using the FuGENE reagent (Promega). Secreted viruses were harvested 48 hr later and cleared by brief centrifugation. For uniform expression of fluorescent reporters and shRNA/rescue constructs, cultures were infected at 5 days in vitro (DIV5) with 100 μ l viral supernatants per 1 ml of medium. This protocol was optimized to achieve >95% infection efficiency. For sparse infection, dissociated neurons were seeded onto Matrigel- (BD Biosciences) coated 12-well plates and treated with viruses immediately after plating. Then 24 hr after infections, cells were washed three times with PBS, dissociated with trypsin, and mixed with non-infected neurons at a 1:20 ratio.

Immunocytochemistry

Neurons attached to the glass coverslips were rinsed once in PBS, fixed on ice in 4% paraformaldehyde (PFA) and 4% sucrose in PBS, and permeabilized for 5 min at room temperature in 0.2% Triton X-100 (Roche). Permeabilized neurons were incubated for 30 min in blocking solution containing 5% BSA (Sigma, fraction V) and 5% normal donkey serum, followed by an overnight incubation with primary and corresponding fluorescently labeled secondary antibodies diluted in the same solution. The coverslips were mounted on glass slides with Aqua-Poly/Mount medium (Polysciences). Images were collected under a Nikon C2 confocal microscope using 10 \times (numerical aperture [N.A.] 0.45), 20 \times (N.A. 0.75), and 60 \times (N.A. 1.40) PlanApo objectives. Digital images were analyzed with the Nikon Elements software package. Digital manipulations were equally applied to all pixels. Analyses of organelle co-localization were performed with NIH ImageJ software.

Immunoprecipitations

Cortices of wild-type mice were homogenized in 20 mM HEPES-NaOH (pH 7.4), 320 mM sucrose, 5 μ g/ml leupeptin, 2 μ g/ml aprotinin, and 1 μ g/ml pepstatin. Membrane fractions were isolated by two sequential steps of centrifugation at 3,000 and 100,000 \times g and solubilized for 1 hr in 20 mM HEPES-NaOH (pH 7.4), 150 mM NaCl, and 1% Triton X-100. Protein extracts were cleared by centrifugation at 100,000 \times g and incubated overnight with sepharose beads (Sigma) coated with anti-SNAP25, anti-SNAP47, or control antibodies. Attached complexes were then washed five times with extraction buffer, eluted from the beads with an SDS gel loading buffer, and used for immunoblotting.

Electrophysiology

Evoked synaptic release was triggered by 1-ms current injections with a local extracellular stimulating electrode (FHC). Postsynaptic currents were monitored in whole-cell mode from randomly selected nearby neurons using a Multiclamp 700B amplifier (Axon Instruments). The frequency, duration, and magnitude of extracellular stimuli were controlled with Model 2100 Isolated Pulse Stimulator (A-M Systems). The whole-cell pipette solution contained 135 mM CsCl₂, 10 mM HEPES-NaOH (pH 7.4), 1 mM EGTA, 1 mM Na-ATP, 0.4 mM Na-GTP, and 1 mM QX-314. The resistance of filled pipettes varied between 3 and 5 M Ω . The bath solution contained 140 mM NaCl, 5 mM KCl, 2 mM CaCl₂, 0.8 mM MgCl₂, 10 mM HEPES-NaOH (pH 7.4), and 10 mM glucose. EPSCs and IPSCs were separated pharmacologically by the addition of picrotoxin (100 μ M) or APV (50 μ M) and CNQX (10 μ M), respectively, to the bath solution. Spontaneous EPSCs and IPSCs were monitored under the same conditions but in the presence of tetrodotoxin (1 μ M). The currents were sampled at 10 kHz and analyzed offline using pClamp10 (Axon Instruments) and Origin8 (Origin Lab) software.

Live Imaging

Conventional fluorescence and TIRF imaging was carried out under the Nikon A1R inverted microscope controlled by the Nikon NIS-Elements software. Images were acquired at 1 Hz with a 12-bit cooled EMCCD camera (Andor,

iXon) using 10× PlanApo (N.A. 0.45), 20× PlanApo (N.A. 0.75), 60× PlanApo (N.A. 1.40), and 100× PlanApo TIRF (N.A. 1.49) objectives. Neurons were bathed in the custom-built chamber perfused at 3–4 ml/min with the NRS solution containing 10 mM HEPES-NaOH (pH 7.4), 140 mM NaCl, 5 mM KCl, 0.8 mM MgCl₂, 2 mM CaCl₂, and 10 mM glucose. The temperature was maintained at 37°C with the lens and stage heaters. Direct depolarization was induced by the application of NRS buffer in which 45 mM NaCl was substituted with KCl. Action potentials were elicited with a pair of parallel platinum electrodes connected to Model 2100 Isolated Pulse Stimulator (A-M Systems). Toxins and inhibitors were diluted in the NRS. The IP of BDNF-pHluorin-positive vesicles was measured after perfusion of de-acidification buffer composed of 10 mM HEPES-NaOH (pH 7.4), 50 mM NH₄Cl, 90 mM NaCl, 5 mM KCl, 0.8 mM MgCl₂, 2 mM CaCl₂, and 10 mM glucose.

Time-Lapse Image Data Analysis

Image stacks were aligned with TurboReg and analyzed with NIH ImageJ/Fiji plugins. Sites of activity-dependent exocytosis (e.g., regions exhibiting a rapid increase in BDNF-pHluorin or SyP-pHluorin fluorescence followed by a characteristic decay) were manually mapped in frames of a fixed size by assigning 0.8 × 0.8 μm regions of interest (ROI). P_r values were calculated as ratios of total numbers of new ENs observed prior to or during excitation to densities of internal reporter-positive vesicles that were automatically counted with FindMaxima NIH ImageJ/Fiji plugin at the end of each trial (following de-acidification with NH₄Cl). Quantifications of exocytosis in specific subcellular domains were performed in sparsely infected neurons co-expressing BDNF-pHluorin and mCherry. A detailed description of TIRF imaging is given in the [Supplemental Experimental Procedures](#).

Statistical Analyses

Statistical analyses were performed with InStat, Prism (GraphPad), and Origin8 (Origin Lab) software. Two groups of data were subjected to Student's t test and Mann-Whitney test. Multiple groups were compared by one-way ANOVA followed by Dunnett's post hoc test or Kruskal-Wallis test.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, eight figures, two tables, and four movies and can be found with this article online at <http://dx.doi.org/10.1016/j.celrep.2015.04.032>.

AUTHOR CONTRIBUTIONS

A.M. and M.S. conceived the experiments. M.S. performed all studies of vesicle trafficking, secretion, and SNARE interaction. J.C. analyzed axon branching in vitro and in vivo. S.P. together with M.S. performed electrophysiological recordings. N.T.-R. and R.S. assisted with generation of expression vectors and data analysis. F.P. supervised axon branching studies. A.M. wrote the manuscript.

ACKNOWLEDGMENTS

We thank the TSRI/DNC faculty members for advice and stimulating discussions; Drs. Thomas Südhof and Martyn Goulding for providing mouse strains and antibodies; Dr. Michael Ehlers for sharing the TfR-pHluorin expression vector; Dr. Kathy Spencer for expert technical assistance; and Elisabeth Rebboah for editing the manuscript. This study was supported by the NIH grants MH085776 and NS087026 (A.M.), Novartis Advanced Discovery Institute (A.M.), The Baxter Foundation (A.M.), Japan Society for Promotion of Science (M.S.), National Institute of Mental Health Pre-doctoral National Research Service Award (R.S.), and Helen Dorris Postdoctoral Fellowship (S.P.).
